97.94.23.2.0.0.5:00.4.5 The problem is that, as I'm just starting learning programming, I really do not know how to correctly code such a process. So here is what I've done: subset data frame to only contain id, distance, and time create a variable for every id that includes both time and distance as follows: $(time*1000)+distance$.T And apply function to this variable: $df2 = \text{apply}(df[2], 1, \text{function}(x)(x*1000)+df[1])$ From what I understand about apply is that it divides the original data frame into sub-data frames and apply function across these, but for the sake of simplicity, I cannot see how this helps me. I am thinking that what I need is to multiply the distance by 1000 and add to the time, and then convert the numbers to the correct data type but I cannot get it to work. I'm really confused and have been searching for hours on Google and reading the documentation, but all that I could find was people describing the same problem as me with different code. Any help would be greatly appreciated! A: If you are willing to use the formula interface in Excel, then the code below will do the work, without extra packages. The Formula interface allows you to perform math in the cell and it works without looping. Below is a sample of the formula interface: $=A1*1,000+B1$ Use the A1 and B1 to substitute the cells where the formula should calculate, and then add the appropriate formula to the rows where the calculation is required. Below is a sample R code for the same. df 82157476af
